Abstract

Common variable immunodeficiency (CVID) is defined by low levels of IgG and IgA, but perturbations in T cells are also commonly found. However, there is limited information on \gamma\delta T cells in CVID patients. Newly diagnosed CVID patients (n = 15) were enrolled before and after intravenous IgG (IVIg) replacement therapy. Cryopreserved peripheral blood mononuclear cells were then used to study \gamma\delta T cells and CVID patients were compared to healthy controls (n = 22). The frequency and absolute count of V\textsubscript{d}1 \gamma\delta T cells was found to be increased in CVID (median 0.60% vs 2.64%, P < 0.01 and 7.5 vs 39, P < 0.01 respectively), while they were decreased for V\textsubscript{d}2 \gamma\delta T cells (median 23.6% vs 0.74%, P < 0.01 and 37.8 vs 13.9, P < 0.01 respectively) resulting in an inversion of the V\textsubscript{d}1 to V\textsubscript{d}2 ratio (0.24 vs 1.4, P < 0.001). Markers of immune activation were elevated on all subsets of \gamma\delta T cells, and HLA-DR expression was associated with an expansion of V\textsubscript{d}1 \gamma\delta T cells (r = 0.73, P = 0.003). Elevated PD-1 expression was found only on V\textsubscript{d}2 \gamma\delta T cells (median 1.15% vs 3.08%, P < 0.001) and was associated with the decrease of V\textsubscript{d}2 \gamma\delta T cells (r = −0.67, P = 0.007). IVIg had no effect on the frequency of V\textsubscript{d}1 and V\textsubscript{d}2 \gamma\delta T cells or HLA-DR expression, but alleviated CD38 expression on V\textsubscript{d}1 \gamma\delta T cells (median MFI 965 vs 736, P < 0.05). These findings suggest that immunological perturbations of \gamma\delta T cells are a general feature associated with CVID and are only partially reversed by IVIg therapy.

Abbreviations: CVID = common variable immunoend, DN = double negative, IVIg = intravenous immunoglobulin, PD-1 = Programmed Death 1.

Keywords: CVID, gamma delta T cells, immune activation, IVIg, PD-1, V\textsubscript{d}1, V\textsubscript{d}2

1. Introduction

Common variable immunodeficiency (CVID) is characterized by low levels of IgG and IgA and/or IgM (2 standard deviations below the normal level) and by an impaired antibody response to vaccination.\textsuperscript{[11]} While some genetic mutations causing CVID have been identified, it is thought to be a polygenic disease with multiple susceptibility loci involved.\textsuperscript{[2]} The poor antibody response in CVID patients results in recurrent infections of the respiratory and gastrointestinal tracts. CVID patients also have an increased incidence of some forms of cancer and autoimmunity,\textsuperscript{[3,4]} probably due to the chronic state of immune activation and loss of key regulatory cells.\textsuperscript{[5-8]} Treatment for CVID consists of IgG replacement that can be given subcutaneous or intravenously (IVIg). Replacement therapy significantly reduces the number of infections\textsuperscript{[9]} and corrects some immune abnormalities,\textsuperscript{[10]} while other perturbations are only partially restored or unchanged.\textsuperscript{[10]}

In humans, \gamma\delta T cells represent between 0.5% and 16% of T cells in the blood with an average of approximately 4%.\textsuperscript{[11]} The major subsets are designated V\textsubscript{d}1 and V\textsubscript{d}2, the latter being the most abundant. Similar to \alpha\beta T cells, \gamma\delta T cells develop in the thymus and undergo gene rearrangement, but they are not subjected to positive selection.\textsuperscript{[12]} They can produce similar cytokines to conventional \alpha\beta T cells, including IL-17,\textsuperscript{[13]} and can also have cytotoxic functions. Following infection, \gamma\delta T cells are activated earlier than \alpha\beta T cells and are involved in the initiation of the inflammatory response.\textsuperscript{[11]} The antigens recognized by \gamma\delta
T cells are very diverse and include phosphoantigens, peptides, and glycolipids. The γδ TCR can also recognize stress-induced ligands. For instance, a Vγ4Vδ5 T cell clone has been shown to recognize EPCR expression on tumor cell and CMV-infected cells.

HIV infection leads to a profound perturbation of the γδ T cells population, characterized by an early expansion of the Vδ1 T cells, while Vδ2 T cells are greatly reduced in number. Vδ2 T cells from HIV patients were also found to have a lower capacity to respond to phosphoantigens. The expansion of Vδ1 T cells has been associated with increased microbial translocation, now recognized as a major contributor of chronic immune activation in HIV infection. CVID patients share several immunological features with HIV patients, namely CD4+ and CD8+ T cell activation, loss of iNKT cells and of regulatory T cells. In contrast to CVID, HIV is characterized by hypergammaglobulinemia, but HIV disease progression is characterized by loss of memory B cell subsets and impaired antibody response to vaccination. Increased microbial translocation has also been suggested to occur in CVID. Two case report studies have shown an increase in γδ T cells in 1 CVID patient each; however, no γδ T cells study has been performed on a larger cohort of CVID patients. We hypothesized that chronic immune activation in CVID patients would lead to perturbations in γδ T cells populations. Thus, we evaluated the frequency and phenotype of γδ T cells in a cohort of CVID patients.

2. Materials and methods

2.1. Study cohort and samples

Fifteen CVID patients (10 females and 5 males aged 6–51, average 34) from the Primary Immunodeficiency Outpatient Clinic of Clinical Immunology and Allergy Division of HC-FMUSP, fulfilling the PagID/ESID criteria (1999) for CVID diagnosis and 22 healthy controls (14 females, 8 males aged 25–45, average 36) were enrolled in the group. Size was based on sample availability. All patients were HIV negative. The study was approved by the Hospital das Clínicas, University of São Paulo Medical School Ethics Committee (CAPesq), and written informed consent was provided by all participants or their legal guardians. Peripheral blood mononuclear cells (PBMC) were isolated by density-gradient sedimentation using Ficoll-Paque (Lymphoprep; Nycomed Pharma, Oslo, Norway). Isolated PBMC were washed twice in Hank balanced salt solution (Gibco, Grand Island, NY), and cryopreserved in RPMI 1640 (Gibco), supplemented with 20% heat inactivated fetal bovine serum (FBS; Hyclone Laboratories, Logan, UT), 50U/mL of penicillin (Gibco), 50 μg/mL of streptomycin (Gibco), 10mM glutamine (Gibco) and 7.5% dimethylsulfoxide (DMSO; Sigma, St Louis, MO). Cryopreserved PBMC from all subjects were stored in liquid nitrogen until used in the assays. For CVID patients, samples were collected before and after initiation of IVlg treatment.

2.2. Flow cytometry and mAbs

Cryopreserved specimens were thawed, washed, and counts and viability were assessed using the Countess Automated Cell Counter system (Invitrogen, Carlsbad, CA). PBMC were washed and stained in Brilliant Violet Stain Buffer (BD Biosciences, San Jose, CA) at room temperature for 15 min in 96-well V-bottom plates in the dark. Samples were then washed and fixed using Cytofix/Cytoperm (BD Biosciences) before flow cytometry data acquisition. mAbs used in flow cytometry: CD3 AF700 (clone UCHT1), CD4 PE-CF594 (clone RPA-T4), CD8 BV711 (clone RPA-T8), CD38 APC-H7 (clone HB7), CD161 BV421 (clone DX12), HLA-DR APC (clone L243), TCR γδ BV650 (clone B1), and PD-1 PE-Cy7 (clone EH12.1) were all from BD Biosciences, TCR Vδ1 FITC (clone TS8.2) was from Abcam (Cambridge, MA), and TCR Vδ2 PE (clone B6) was from Biologend (San Diego, CA). Live/dead aqua fixable cell stain was from Life Technologies (Eugene, OR). All antibodies were used together in 1 panel. A minimum number of 200 events were recorded for all subsets of γδ T cells. Data were acquired on a BD LSRFortessa instrument (BD Biosciences) and analyzed using FlowJo Version 9.8.5 software (TreeStar, Ashland, OR).

2.3. Statistical analysis

All statistical analyses were performed using Graph Pad Prism version 6.0f for Mac OSX (GraphPad Software, La Jolla, CA). The comparison between healthy controls and CVID patients was analyzed using Mann–Whitney U test and changes after IVlg initiation in CVID patients were analyzed with Wilcoxon matched-pairs signed rank test. Nonparametric analyses were performed because the data were not normally distributed. Associations between groups were determined by Spearman rank correlation. P values <0.05 were considered statistically significant.

3. Results

3.1. Expansion of Vδ1+ and loss of Vδ2+ in CVID

Table 1 shows the demographic details of the subjects included in this study. We used cryopreserved PBMCs samples from a treatment naive cohort of CVID patients followed 9 to 15 months after initiation of monthly intravenous immunoglobulin replacement therapy (400–600 mg/kg) to study γδ T cells by flow cytometry. The viability of the thawed PBMC was over 95% and there was no difference in the viability between the groups. First, we evaluated the frequency of the Vδ1+, Vδ2+, and Vδ1–Vδ2− γδ T cells subsets in healthy controls and in treatment naive CVID patients. In healthy controls, Vδ1+ cells typically represented less than 1% of the T cells and Vδ2+ represented the major subset of γδ T cells (Supplementary file 1, http://links.lww.com/MD/B140). Supplementary file 2, http://links.lww.com/MD/B141 summarized all comparisons between CVID patients and healthy controls. In CVID patients Vδ1+ were significantly increased (median 0.60% vs 2.64%, P < 0.01) while Vδ2+ were reduced (median, 2.36% vs 0.74%, P < 0.01) compared with healthy controls (Fig. 1A). The frequency of the Vδ1+ Vδ2− γδ T cells subsets was also increased in CVID patients (Fig. 1A, median 0.39% vs 0.58%, P < 0.05). Overall, this led to a significant increase in the ratio of Vδ1+ to Vδ2+ (Fig. 1B, 0.24 vs 1.4, P < 0.001). Importantly, the frequency of all subsets of γδ T cells was not changed after IgG replacement therapy (median 2.64% vs 5.23%, P = 0.17; 0.74% vs 1.33% P = 0.38; 0.59% vs 0.60%, P = 0.21 for Vδ1+, Vδ2+, and Vδ1− Vδ2− γδ T cells respectively).

Next, we compared the absolute count of each subset of γδ T cells in CVID patients to those observed in healthy controls. Again, Vδ1+ were increased (median 7.5 vs 39, P < 0.01) and Vδ2+ were decreased (median 37.8 vs 13.9, P < 0.01; Fig. 1B). However, the absolute count of Vδ1+ Vδ2− γδ T cells was normal in
CVID patients (median 7.3 vs 9.5, \(P=0.69\); Fig. 1B). The absolute count of all subsets of \(\gamma\delta\) T cells was not affected by IVIg (median, 39 vs 78.3 \(P=0.81\); 13.9 vs 23.9, \(P=0.58\); 9.5 vs 7.9 \(P=0.69\) for \(V_{d1}^+\), \(V_{d2}^+\), and \(V_{d1}/C0\ V_{d2}/C0\) \(\gamma\delta\) T cell respectively).

Thus, our results suggest a specific expansion of \(V_{d1}^+\) and loss of \(V_{d2}^+\) subsets in CVID.

3.2. Differential redistribution of CD4\(^+\) and CD8\(^+\) on \(\gamma\delta\) T cells in CVID

We evaluated the distribution of CD4 and CD8 expression on \(\gamma\delta\) T cells for each of the \(\gamma\delta\) T cells subsets individually. As expected, the major population for all subsets of \(\gamma\delta\) T cells was double negative (DN). CD4 expression was reduced for \(V_{d1}^+\) and \(V_{d1}/C0\ V_{d2}/C0\) \(\gamma\delta\) T cells in CVID (median 11.6% vs 1.74%, \(P<0.01\); 27.5% vs 8.04%, \(P<0.001\) respectively; Fig. 2A). \(V_{d1}^+\) presented an increased DN population while the CD8 population was increased for \(V_{d1}/C0\ V_{d2}/C0\) \(\gamma\delta\) T cells (median 45.5% vs 64.4%, \(P<\) 0.01; 29.6% vs 32.4%, \(P=0.05\); Fig. 2B and C). On the other hand, CD4 and CD8 expression was normal on \(V_{d2}^+\) cells (median 2.62% vs 3.12%, \(P=0.96\); 29.6% vs 32.4%, \(P=0.04\) respectively). Expression of CD4 and CD8 on all subsets of \(\gamma\delta\) T cells was not changed after IVIg. Thus, our results show that \(\gamma\delta\) T cells subsets in CVID have differential distribution of CD4 and CD8 expression.

3.3. High levels of \(\gamma\delta\) T cells activation in CVID

CVID is characterized by elevated CD4\(^+\) and CD8\(^+\) T cell activation,\(^{[6]}\) therefore, we hypothesized that \(\gamma\delta\) T cells also had high levels of activation. We observed elevated levels of CD38, HLA-DR and coexpression of CD38 and HLA-DR on \(V_{d1}^+\) (median MFI 576 vs 965, \(P<0.001\); 44.9% vs 73.1%, \(P<0.01\; 30.5% vs 50.3%, \(P<0.001\) respectively), \(V_{d2}^+\) (median MFI 99.1 vs 299, \(P<0.01\); 18.1% vs 44.9%, \(P<0.01\); 8.41% vs 17.2%, \(P<0.001\) respectively), and \(V_{d1}/C0\ V_{d2}/C0\) \(\gamma\delta\) T cells (median MFI 652 vs 968, \(P<0.01\); 43.7% vs 65.6%, \(P<0.01\); 26.1% vs 49%, \(P<0.001\) respectively, Fig. 3A–C) confirming our hypothesis. Following replacement therapy CD38 levels and CD38 and HLA-DR coexpression were reduced only on \(V_{d1}^+\) (median MFI 965 vs 736, \(P<0.001\); 50.3% vs 38.3%, \(P<0.05\) respectively; Fig. 3A and C) but remained higher compared with healthy controls (median MFI 576 vs 736, \(P<0.05\); 30.5% vs 38.3%, \(P<0.05\) respectively).

3.4. Elevated PD-1 expression by Vδ2+ T cells in CVID

Programmed death 1 (PD-1) is an inhibitory receptor and its expression is associated with immune exhaustion in chronic infections. We have previously reported that PD-1 expression is elevated on CD4+ T cells in CVID. Thus, we investigated PD-1 expression by γδ+ T cells in CVID. We observed that PD-1 expression was normal on Vδ1+ and Vδ1/Vδ2-γδ+ T cells (median, 33.0% vs 43.0%, \( P = 0.22 \); 33.9% vs 32.7%, \( P = 0.88 \) respectively) but elevated on Vδ2+ (median 1.15% vs 3.08%, \( P < 0.001 \); Fig. 4A). PD-1 remained elevated on Vδ2+ after immune reconstitution (median 1.15% vs 3.09%, \( P < 0.001 \); Fig. 4A) but was reduced on Vδ1+ (median 43.0% vs 36.5%, \( P < 0.05 \)).

3.5. Activation and exhaustion are associated with γδ T cells frequency in CVID

Finally, we investigated if the elevated levels of activation and exhaustion could be associated with the change in γδ T cells frequency that we observed. HLA-DR expression was positively associated with the frequency of Vδ1+ and Vδ1-Vδ2-γδ+ T cells (\( r = 0.73, P = 0.003 \); \( r = 0.68, P = 0.006 \) respectively; Fig. 5A and B) but not with Vδ2+ T cell frequency (\( r = 0.022, P = 0.94 \); Fig. 5C) in treatment naive CVID patients. Vδ2+ T cell frequency was negatively associated with PD-1 expression (\( r = -0.67, P = 0.007 \); Fig. 5D).

4. Discussion

Previous case reports described an expansion of γδ T cells in 2 CVID patients and this expansion was associated with Mycobacterium infection for one of them. Our findings now suggest that perturbations in γδ T cells are a general feature of CVID patients. We observed an increase of Vδ1+ and a decrease of Vδ2-γδ T cells in CVID, leading to an inversion of the Vδ1+ to Vδ2-γδ T cell ratio. Interestingly, the majority of sulfatide reactive type II NKT cells have been described to express Vδ1,[27] however it remains to be determined if this population of type II NKT cells is expanded in CVID patients together with Vδ1+ γδ T cells or reduced like type I NKT cells.[28,29]

Vδ2-γδ T cells are known to interact with many immune cells to shape immune responses, including B cells to stimulate humoral immunity[30] and activated Vδ2-γδ T cells have been shown to act as antigen-presenting cells.[31,32] Furthermore, Vδ2-γδ T cells can recognize mevalonate metabolites in tumor cells and are believed to have an important antitumor activity.[33] Therefore, loss of this cell population could partially explain some of the immunological perturbation seen in CVID and the increased incidence of some forms of cancer. More studies are required to determine if the reduced frequency of Vδ2-γδ T cells in the blood of CVID patients is due to redistribution to tissues or to a complete loss of those cells. More studies are also needed to evaluate the functionality of the remaining Vδ2-γδ T cells. A mutation in Vav1 has been associated with impaired Th2
response in a subset of CVID patients, more experiments are needed to assess the impact of this mutation on γδ T cell functionality.

The high levels of activation of all subsets of γδ T cells that we report here were not affected by IVIg treatment, suggesting that IVIg is not controlling the factors responsible for γδ T cells activation. However, it is possible that a longer period of time on replacement therapy is needed to observe a reduction in γδ T cells activation. There is now accumulating evidence that IgG replacement does not restore a normal immune system in CVID. Complementary therapies aiming to restore normal cellular immunity should be considered and could prevent some of the complications associated with CVID. Long-term low-dose IL-2 has been shown to enhance T cell function in CVID patients but other compartments of the cellular immune system were not studied.

Interestingly, the expansion of Vδ1+ and the reduction in Vδ2+ γδ T cells in CVID is similar to that which has been described for
HIV infection,\textsuperscript{[16]} suggesting that common drivers in the pathology associated with primary and secondary immunodeficiency might exist. In this regard, microbial translocation has been implicated in the inversion of the V\textsubscript{d}1 to V\textsubscript{d}2 ratio in SIV infection\textsuperscript{[19]} and in CD4 T cell exhaustion in CVID.\textsuperscript{[23]} Expansion of V\textsubscript{d}1+ and V\textsubscript{d}1/C0 V\textsubscript{d}2/C0 gd+ T cells in CVID was associated with activation, suggesting an implication for chronic inflammation in expending those subsets of gd T cells. Therefore, we propose that inversion of the V\textsubscript{d}1 to V\textsubscript{d}2 ratio in CVID is a reflection of the infection burden.

 Altogether, our results suggest that IVIg replacement therapy is not sufficient to normalize change in gd T cells frequency and activation in CVID. Furthermore, our results add to the list of similarities between primary and secondary immunodeficiencies, such as HIV infection.
